Consider the problem of estimating a vector $x$ from measurements $y$ given by the relationship

$$y = Ax + \epsilon, \quad \epsilon \sim \mathcal{N}(0,1).$$

The variance-covariance matrix of such an estimator is proportional to $(A^T A)^{-1}$. A reasonable goal during the design phase of an experiment would therefore be to minimize $(A^T A)^{-1}$ in some way.

There are many different ways in which $(A^T A)^{-1}$ might be made minimal. For example, minimization of the trace of $(A^T A)^{-1}$ (A-Optimality), minimization of the maximum eigenvalue of $(A^T A)^{-1}$ (E-Optimality), minimization of the determinant of $(A^T A)^{-1}$ (D-Optimality), and maximization of the trace of $A^T A$ (T-Optimality) all have their merits.

Perhaps the most commonly used of these optimality criteria is D-Optimality, which is equivalent to maximizing the determinant of $A^T A$. Typically, the rows of $A = [a_1, \ldots, a_q]^T$ are chosen from $M$ possible test vectors $u_i \in \mathbb{R}^p, i = 1, \ldots, M$, which are known in advance. That is,

$$a_i \in \{u_1, \ldots, u_M\}, \quad i = 1, \ldots, q$$

Given that the matrix $A$ is made up of these test vectors $u_i$, the matrix $A^T A$ can be written as

$$A^T A = q \sum_{i=1}^{M} \lambda_i u_i u_i^T$$

(1)

where $\lambda_i$ is the fraction of rows in $A$ that are equal to the vector $u_i$ [2]. Then, the the D-optimal experimental design problem can be written as a minimum determinant problem [2]

$$\text{minimize} \quad \log \det \left( \sum_{i=1}^{M} \lambda_i u_i u_i^T \right)^{-1}$$

subject to

$$\sum_{i=1}^{M} \lambda_i = 1 \quad \lambda_i \geq 0, \quad i = 1, \ldots, m$$

Due to the inequality constraint, this primal formulation cannot be interpreted as a primal SQLP. By defining $Z = u \ diag(\lambda) \ u^T$, the dual problem is ([11])

$$\text{maximize} \quad \log \det (Z)$$

subject to

$$-\sum_{i=1}^{p} \lambda_i (u_i u_i^T) + Z = 0, \quad Z \in S^p$$

$$-\lambda + z' = 0, \quad z' \in \mathbb{R}_+^p$$

$$1^T \lambda = 1, \quad \lambda \in \mathbb{R}^p$$

We proceed with writing the D-Optimal design problem as an SQLP by first considering the objective function. The objective function depends only on the determinant of the matrix variable $Z$, which is the log-barrier. This indicates
that the variable $v^s$ in the dual equation is equal to 1 in this formulation, while $v^q$ and $v^l$ are both zero. Since $\lambda$ does not appear in the objective function, the vector $b$ is equal to $0$.

The constraint matrices $A$ are easy to define in the case of the dual formulation, as they multiply multiply $\lambda$. In the first constraint, each $\lambda_i$ is multiplied by the matrix formed by $-u_i u_i^T$, so define $A_i$ to be

$$A_i = -u_i u_i^T, \quad i = 1, \ldots, p.$$ 

Then, the constraint matrix is $A^s = [svec(A_1), \ldots, svec(A_p)]$. In the second constraint containing the linear variable $z^l$, the constraint matrix is $A^l = -I_p$, and in the third constraint containing only the unconstrained variable $\lambda$, the constraint matrix is $A^u = 1^T$. Since there is no quadratic variable, $A^q = 0$.

Finally, define the right hand side of each constraint

$$C^s = 0_{n \times n}$$

$$C^l = 0_{p \times 1}$$

$$C^u = 1$$

which fully specifies the D-Optimal design problem as an SQLP.

To convert this to a form usable by sdpt3r, we initialize our input variables by noting we have three blocks - $X$, $z^l$, and $\lambda$.

As before, we declare the three blocks in $blk$. The first block is semidefinite containing the matrix $Z$, the second a linear block containing $z^l$, and the third an unrestricted block containing $\lambda$.

```r
R> blk <- c("s" = n, "l" = p, "u" = 1)
```

Next, by noting the variable $\lambda$ does not appear in the objective function, we specify $b$ as a vector of zeros.

```r
R> b <- matrix(0,nrow=p,ncol=1)
```

Next, looking at the right-hand side of the constraints, we define the matrices $C$.

```r
R> C1 <- matrix(0,nrow=n,ncol=n)
R> C2 <- matrix(0,nrow=p,ncol=1)
R> C3 <- 1
R> C <- list(C1,C2,C3)
```

Finally, we construct $At$ for each variable.

```r
R> A <- matrix(list(),nrow=p,ncol=1)
```

```r
R> for(k in 1:p){
R>   A[[k]] <- -uk %*% t(uk)
R> }
```

```r
R> A1 <- svec(blk[1], A,1)
R> A2 <- diag(-1,nrow=p,ncol=p)
R> A3 <- matrix(1,nrow=1,ncol=p)
R> At <- list(A1,A2,A3)
```

The final hurdle necessary to address in this problem is the existence of the log-barrier. Recall that it is assumed that $v^s, v^q, \text{ and } v^l$ in the dual problem are all zero in OPTIONS. In this case, we can see that is not true, as we have a log term containing $Z$ in the objective function, meaning $v^q$ is equal to one. To pass this to sqlp, we define the OPTIONS$parbarrier variable as
The D-Optimal experimental design problem can now be solved using sqlp

R> sqlp(blk, At, C, b, control)

To demonstrate the output generated from a D-optimal experimental design problem, we consider a simple $3 \times 25$ matrix containing the known test vectors $u_1,...,u_{25}$ (the data is available in the sqlp package). To solve the problem using sqlp, we use the function doptimal, which takes as input an $n \times p$ matrix $U$ containing the known test vectors, and returns the optimal solution using sqlp. The output we are interested in is $y$, corresponding to $\lambda$ in our formulation, the percentage of each $u_i$ necessary to achieve maximum information in the experiment.
